Abstract—The increasing complexity of the software development based on peer to peer networks makes necessary the definition of new frameworks in order to simplify the developer tasks. Additionally, some applications, e.g. fire detection or security alarms may require real time constraints and the high level definition of these features eases the application development. In this paper, a service model based on a component model with real-time features is proposed. The high-level model will abstract developers from implementation tasks, such as discovery, communication, security or real time requirements. The model is oriented to deploy services over small mobile devices, such as sensors, mobile phones and PDAs, where the computation is light-weight. Services can be composed among them by means of the port concept to form complex ad-hoc systems and their implementation is carried out using a component language called UM-RTCOM. In order to apply our proposal, a fire detection application is described.

Keywords—Peer-to-peer, mobile systems, real-time, Service-Oriented Architecture.

I. INTRODUCTION

Peer-to-peer (P2P) systems [1] represent a new challenge in the development of software for distributed systems and an interesting alternative to centralized and client-server models. Each node in the P2P network is symmetrical and the mechanisms of communication are based on dynamic ad-hoc networks among peers. The P2P approach can be ported to mobile systems, which are composed by a set of nodes intending to cooperate, while they are entering/leaving the network continuously. Some mixed approaches keep a minimum part of infrastructure and central control, but our proposal is focussed on pure ad-hoc systems. Examples of this type of system are sensor networks [2], consisting of spatially distributed autonomous devices using sensors to cooperatively monitor physical or environmental conditions; and MANET (Mobile Ad-hoc NETworks) [3], self-configuring network of mobile devices such as PDAs and mobile phones connected by wireless links.

Due to the increasing complexity of the development of applications based on the P2P architecture, new high level programming models are necessary in order to simplify the developer tasks. This paper presents a component-based service model to enable developers to specify P2P applications. The model allows us to define the services that peers can provide or require in the network. The access points to the peer services are the ports that define the commands and events that other peers can require. P2P applications can need to define real time requirements, as example, the establishment of a priority order to attend to service queries. In this sense, the model allows us to include real time constraints in the ports, that is, developers can assign to commands and events characteristics as service periods, priorities or deadlines. This way, two services would be able to be required simultaneously in the peer and priority would establish an ordered delivery. Additionally, the period would allow us to receive events without carrying out the invocation. The proposed model is platform independent and tools can be defined in order to map the specification to the necessary implementation as example using Windows peer-to-peer networking [4] on Windows platforms or JXTA [5] on Java platforms. The service implementation is carried out using the component based paradigm by means of the component language UM-RTCOM [6]. It proposes a distributed model based on lightweight component composition with real-time features. The UM-RTCOM specification is also platform independent and includes the possibility of defining real time requirements.

The Service-Oriented Architecture (SOA) has been successfully applied in a lot of infrastructure-based and client-server model based distributed systems, being Web Services the most known standard [7]. Recently, some work based on the (SOA) paradigm oriented to P2P systems has appeared. The following list shows some related work. They mainly differ from our approach because either they do not provide a high level abstraction model that facilities the application programmer task or they are focused on infrastructure based systems:

- The JXTA platform, is a set of simple, open source P2P protocols that enable any device on the network to communicate, collaborate, and share resources. It is a useful tool to implement P2P systems, but in complex systems can be difficult to apply without an abstract model. It is a good platform to support a service model.
- JMobiPeer [8], developed in the University of Catania, proposes an alternative to JXTA more oriented to MANETs. It tries to solve the faults existing in the JXME version of JXTA at the moment of the development.

This work is supported by the EU funded project FP6 IST-5-033563 and the Spanish project TIN2005-09405-C02-01.
However, it does not offer an abstraction model.

- DeEvolve [9] approaches the problem giving a flexible notation for the composition of services including the handling of exceptions such as failure of peers. It is based on JXTA and offers an exception handling mechanism to control the peer failures. It is oriented to infrastructure-based P2P systems.

- The middleware for wireless sensor networks (WSNs) presented in [10], provides a layer between user applications and the network. Such middleware offers an automatic choice of the network configuration and data dissemination strategy. It is implemented in Java and use the XML language and the SOAP protocol for representing all application communications.

- The work proposed in [11] tries to build a middleware for WSNs that is based on the service-oriented architecture using Web services and Grid technologies. They include probability models in order to improve the quality of service for service-oriented WSN applications.

In the following sections a concise explanation of the UM-RTCOM model and a detailed vision of the proposed model are presented in (Section III) and (Section II), respectively. Additionally, in Section IV a fire detection system example is described using our approach. Finally, in Section V some conclusions and future work are sketched.

II. THE UM-RTCOM MODEL

UM-RTCOM is based on light-weight components which do not depend on any specific execution platform or heavy framework. Instead, UM-RTCOM components are developed in a platform independent way and are later deployed in specific platforms like executable or libraries with a minimum overhead. In addition, UM-RTCOM components are complemented by an abstract model of their behavior (based on SDL). This abstract model allows to perform different analysis types such as for example real-time analysis, deadlock freedom, liveness properties, etc. In this sense, a UM-RTCOM component is the sum of the code and abstract model.

The model improves some features of standard component models, adding constructions to express temporal constraints, synchronization, quality of service, events, etc. It is a hierarchical model where components act like containers of other components and, at the same time, provide interfaces.

A. Component Types

There are two main component types: primitive and generic. Generic components are the standard components of the model. They provide services through interfaces and can require services of other generic components. On the other hand, primitive components (active or passive) are contained in generic components. They are the basis for building generic components, representing execution threads or shared resources.

1) Generic Components: These components are the basis of the model. They act like containers of other components, generic or primitive, and they can be composed of other generic components in order to complete their functionality.

A generic component has a public definition part with the provided and required interfaces, and an implementation part which includes the implementation of the services offered. The model distinguishes between input interfaces (provided) and output interfaces (required).

UM-RTCOM also allows events to be used through the declaration of produced and consumed events. In this programming-style, a component declares what events produce and what events consume. This way, components can communicate with each other without common interfaces.

2) Active Components: These components are primitive elements used to to express “execution flows” inside a generic component. Concurrency is an important factor in real-time systems, so we use first-order elements to model it. In addition, the use of these components is also motivated by the later analysis phases.

Active components are responsible for the execution flow inside generic components through the interaction with other elements such as passive components or generic components. Active components are also responsible for the treatment of the invocation requests on the generic container. Thus, the response to incoming requests is delegated to these primitive components.

The utilization of an Active component requires a definition part and a declaration part. In the definition part, the component defines a special “execute” method to be invoked by the system in different ways: time-triggered, event-triggered, service requests, etc.

3) Passive Components: Shared resources are another important element in embedded and real-time systems. Passive components are primitive elements which allow us to use shared resources in the model. Basically, they cannot initiate any action and offer some basic services which can be invoked from active components. This behavior is used in order to facilitate later analysis phases. Passive components provide mutual exclusion with priority ceiling mechanisms which avoid priority inversions.

- DeEvolve [9] approaches the problem giving a flexible notation for the composition of services including the handling of exceptions such as failure of peers. It is based on JXTA and offers an exception handling mechanism to control the peer failures. It is oriented to infrastructure-based P2P systems.
- The middleware for wireless sensor networks (WSNs) presented in [10], provides a layer between user applications and the network. Such middleware offers an automatic choice of the network configuration and data dissemination strategy. It is implemented in Java and use the XML language and the SOAP protocol for representing all application communications.
- The work proposed in [11] tries to build a middleware for WSNs that is based on the service-oriented architecture using Web services and Grid technologies. They include probability models in order to improve the quality of service for service-oriented WSN applications.

In the following sections a concise explanation of the UM-RTCOM model and a detailed vision of the proposed model are presented in (Section III) and (Section II), respectively. Additionally, in Section IV a fire detection system example is described using our approach. Finally, in Section V some conclusions and future work are sketched.

II. THE UM-RTCOM MODEL

UM-RTCOM is based on light-weight components which do not depend on any specific execution platform or heavy framework. Instead, UM-RTCOM components are developed in a platform independent way and are later deployed in specific platforms like executable or libraries with a minimum overhead. In addition, UM-RTCOM components are complemented by an abstract model of their behavior (based on SDL). This abstract model allows us to perform different analysis types such as for example real-time analysis, deadlock freedom, liveness properties, etc. In this sense, a UM-RTCOM component is the sum of the code and abstract model.

The model improves some features of standard component models, adding constructions to express temporal constraints, synchronization, quality of service, events, etc. It is a hierarchical model where components act like containers of other components and, at the same time, provide interfaces.

A. Component Types

There are two main component types: primitive and generic. Generic components are the standard components of the model. They provide services through interfaces and can require services of other generic components. On the other hand, primitive components (active or passive) are contained in generic components. They are the basis for building generic components, representing execution threads or shared resources.

1) Generic Components: These components are the basis of the model. They act like containers of other components, generic or primitive, and they can be composed of other generic components in order to complete their functionality.

A generic component has a public definition part with the provided and required interfaces, and an implementation part which includes the implementation of the services offered. The model distinguishes between input interfaces (provided) and output interfaces (required).

UM-RTCOM also allows events to be used through the declaration of produced and consumed events. In this programming-style, a component declares what events produce and what events consume. This way, components can communicate with each other without common interfaces.

2) Active Components: These components are primitive elements used to to express “execution flows” inside a generic component. Concurrency is an important factor in real-time systems, so we use first-order elements to model it. In addition, the use of these components is also motivated by the later analysis phases.

Active components are responsible for the execution flow inside generic components through the interaction with other elements such as passive components or generic components. Active components are also responsible for the treatment of the invocation requests on the generic container. Thus, the response to incoming requests is delegated to these primitive components.

The utilization of an Active component requires a definition part and a declaration part. In the definition part, the component defines a special “execute” method to be invoked by the system in different ways: time-triggered, event-triggered, service requests, etc.

3) Passive Components: Shared resources are another important element in embedded and real-time systems. Passive components are primitive elements which allow us to use shared resources in the model. Basically, they cannot initiate any action and offer some basic services which can be invoked from active components. This behavior is used in order to facilitate later analysis phases. Passive components provide mutual exclusion with priority ceiling mechanisms which avoid priority inversions.
B. Component Interactions

Communication between components is performed through interfaces and events. UM-RTC0M provides synchronization primitives (wait, call, raise) which allow services and events to be invoked, raised or waited.

- Wait Primitive: This primitive is used to waiting for new invocations on services or the creation of consumed events. It is used in Active components.
- Call Primitive: Primitive call is used to invoke services of generic components. It can be used in Active or Passive components.
- Raise Primitive: This primitive is used to raise events in an asynchronous way. When a component raises an event, this event is caught by all the components that consume that event.

Fig. 1 shows an example where two generic components (Generic1 and Generic2) are interconnected. The example shows how the Active component Generic1::MyActive1 calls the method I1::method1 provided by Generic2 where the request is attended to by Generic2::MyActive2 through the wait primitive.

C. Real-time Constraints Specification

The user can indicate real-time constraints in the components. This is a very important element which is not included in other component models. This way, the user specifies the requirements regarding how a component is used.

The only elements visible of a component are the interfaces and events. The user can specify temporal constraints for methods or events indicating the minimum period between two invocations or a deadline for completing the request.

III. THE CoSP2P MODEL

The proposed work is a service-based model, oriented to peer-to-peer systems without infrastructure, where developers can define services to be offered by network nodes. It also specifies how these services can be composed in order to create distributed applications and declare the necessary ports so that each node has access to the services offered by other nodes. Additionally, real-time constraints can be specified to the links between services in order to form systems with timing requirement in P2P environments.

Fig. 2 shows a graphical example of a service-composition scheme. The inward sense of port means that the port is provided. Optional ports are drawn in dark color. Moreover, components and ports are connected by means of dash-dotted lines. Although it is not shown in this figure, a peer can provide more than one service. In the example, the service offered by Peer A requires three different ports in order to be provided: the ports offered by B and C are required and the port offered by D is optional.

CoSP2P is an intermediate layer (Fig. 3) that allows applications to be developed composing services using components defined with the UM-RTC0M model.

Port MyPort {
    command GetValue(out int value);
    event High
}
Fig. 4. Model Syntax.

MyPort defines a command named GetValue, with one output parameter, and an event called High. The real-time restrictions can be established to commands and events declared in a port declaration. These restrictions are specified by the keywords Priority, Deadline and Period.

- **Priority**: This primitive allows us to define the priority of commands and events.
- **Deadline**: This restriction defines the maximum execution time for a command.
- **Period**: This primitive allows us to establish the execution period for an event.

The previous example shows the definition of a command and an event; MyCommand has a five-second deadline constraint and a priority of 5 is assigned; MyEvent has an execution period of one-second and a priority of 10 is assigned.

### B. Service Definition

A service definition is composed of: firstly, a service description that is followed by the ports that are going to take part in the service. The port enumeration is divided in three types: provided_ports, required_ports and optional_ports:

- **Provided ports**: Ports that the service offers to other services. The rest of nodes can query to this service through the provided ports.
- **Required ports**: Ports that a service needs in order to be executed. Other nodes in the network must offer these services.
- **Optional ports**: These ports are associated with non-critical services, e.g., ports used to monitor the system.

Finally, it is possible to define communication groups so that a service can communicate with services of the same group. A service can belong to one or several groups.

The code below represents a service definition; first, we write a brief description, then, we define that the service provides one port (MyPort) and only one port is required (OtherServicePort). In this example, the service has no optional ports. Finally, we specify that MyService belongs to the ExampleGroup group.

```java
Service MyService {
    Description = "Example service";
    Provides MyPort;
    Requires OtherServicePort;
    Groups ExampleGroup;
}
```

### C. Service Implementation

When a service has been specified, its implementation must be declared:

1. **Firstly,** the components that implement the service are defined. The final implementation is carried out by the UM-RTCOM components.
2. **Secondly,** the connection between ports and UM-RTCOM components must be specified. This is done in the port binding declaration. In this block, port commands and events are linked to the component commands and events.
3. **Thirdly,** since a service can be implemented by various components, it is necessary to declare how each component is composed with the rest. This is specified by following the UM-RTCOM model syntax.

```java
Service implementation MyService {
    Components AComponent component;
    PortBind
    {
        MyPort.GetValue = component.GetValue;
        MyPort.High = component.High;
        OtherServicePort.GetTemp = component.GetTemp;
        OtherPeerPort.TempHigh = component.TempHigh;
    }
    ... Component composition ...
}
```

### IV. Example

In this section, we present a practical application that has been considered to test the component-based service model. First, we show a brief description of the system, then we detail the different parts of our solution describing the design of the ports and services used and, finally, some implementation details are sketched.
A. System Description

The example constitutes a sensor and actor network in order to monitor and control a fire in a building (Fig. 5). We require four types of peers: the fire detector peer is an actor that is able to detect a possible fire and then acts accordingly. The temperature-sensor and smoke-sensor peers provide temperature and smoke level measurement, respectively. The monitor peer receives data related to the actions carried out by the fire detector, as well as updates the temperature and smoke threshold values used to trigger the corresponding events.

The system is composed of only one fire detector, but there could be one or more temperature/smoke sensors per room and any number of monitors. In order to provide the fire detection service, at least one temperature sensor and one smoke sensor must be available. Therefore, temperature and smoke ports are required but monitor ports are optional.

The group creation can be made in many ways, for example one possible solution could be to form a group for each room and another for all monitors or simply one group for all communications. Finally, in our example we have proposed three kinds of groups (Fig. 6):

- **Temperature group**: where temperature sensors and the fire detector communicate each other.
- **Smoke group**: composed of smoke sensors and the fire detector.
- **Monitor group**: the fire detector sends all monitor peers the information about building fire control.

B. Designing the Fire Detector System with CoSP2P

In order to create a system based on service composition, we must define the ports that will be provided by services, and it is also necessary to describe services and their implementations.

In the proposed system four ports exist, one for each service, although a service can usually provide more than one. For example a calculator service may provide two types of ports, one for standard calculus and another for scientific one.

In the example below, the temperature port offers a command to obtain the temperature and raises an event when the temperature is higher than a threshold. The smoke port is defined in the same way as the temperature port and the monitor port has only one command to get data to display it on screen.

```plaintext
Port PTemperature {
  command GetTemp(out float data, out Unique id)
  constraints Deadline 5000;
  event TempHigh constraints Priority 5;
}
Port PSmoke {
  command GetSmoke(out float data, out Unique id)
  constraints Deadline 5000;
  event SmokeHigh constraints Priority 10;
}
Port PMonitor {
  command DisplayData(in String data)
}
```

As stated before, it is possible to define deadline constraints in commands. In this case, the commands GetTemp and GetSmoke have five seconds as maximum execution time. The developer must decide what to do when the execution time is exceeded. Furthermore, the priority constraint allows us to define the priority of port commands and events. In the example, priorities of 5 and 10 are assigned to events TempHigh and SmokeHigh respectively.

The definition of the temperature service is really short. It includes a brief description, provides the temperature port and specifies that it belongs to the temperature group.

```plaintext
Service STemperature {
  Description "...";
  Provides PTemperature;
  Groups TempGroup;
}
```

As defined in section IV-A, the fire detector service requires that at least one port of each sensor type is available. The monitor port is optional. Moreover, this service belongs to the three groups.

```plaintext
Service SFireDetection {
  Description "...";
  Provides PFire;
  Requires PTemperature, PSmoke;
  Optional PMonitor;
  Groups TempGroup, SmokeGroup, MonitorGroup;
}
```

Finally, the implementations of the temperature and fire detection services are the following:
Service implementation STemperature {
    Components Temperature temp, ...;
    Port bind {
        PTemperature.GetTemp = temp.TempData;
        PTemperature.TempHigh = temp.TempHigh;
    } ... Component composition ...
}

Service implementation SFireDetection {
    Components Control control, Alarm alarm, Sprinkler sprinkler;
    Port bind {
        PFireDetection.CheckFire = control.CheckFire;
        PFireDetection.Fire = control.Fire;
        PTemperature.GetTemp = control.TempData;
        PTemperature.TempHigh = control.TempHigh;
        PSmoke.GetSmoke = control.SmokeData;
        PSmoke.SmokeHigh = control.SmokeHigh;
        PMonitor.DisplayData = control.DisplayData;
    } ... Component composition ...
}

It is only necessary to include on the one hand, the list of components that are going to be bound with the service ports and, on the other hand, the component composition using the UM-RTC model as we described previously.

It is important to indicate that it is possible to define different components to provide the same service.

C. Implementation

In order to test the proposed service model, a first prototype has been implemented. The model allows developers to define systems independently of the platform and the programming language. We decided to implement our application example using “Windows Peer-to-Peer Networking”, but it can also be realized on the JXTA peer-to-peer framework with the same design.

The application can provide the four services that have been described. Fig. 7 shows the fire detector screen with three temperature peers and three smoke peers connected. On the other hand, Fig. 8 depicts screenshots of the other three peers; the temperature sensor and the smoke sensor only show their sensor values, and the monitor peer contains a list with fire detector information (connection and disconnection of sensors, high values of temperature or smoke, fire detector actions, etc.).

The implementation has been tested on top of an ad-hoc network using a laptop for each peer.

Fig. 7. Fire Detector Screen.

Fig. 8. Temperature Sensor, Smoke Sensor and Monitor Screens.

V. CONCLUSIONS AND FUTURE WORK

In this paper we have presented CoSP2P, a novel component-based service model for peer-to-peer systems. We propose a syntax to describe this kind of systems independently of the programming language or operative system used. The model provides the possibility of including real-time constraints in order to form systems with timing requirement in P2P environments. Furthermore, with the description of a fire detector system, we have deployed an application using “Windows Peer-to-Peer Networking” in order to assess the model expressiveness.

As future work, we are currently extending the model syntax, as well as port and service definitions, including declarations of the peers and groups that can take part in a system. On the other hand, we intend to include an exception handler, to provide a semantics to group formation and to develop, using proxyless JXTA, the described system with the proposed model.
